ABSTRACT

A neural model of motion perception simulates psychophysical data concerning first-order and second-order motion stimuli, including the reversal of perceived motion direction with distance from the stimulus (T display), and data about directional judgments as a function of relative spatial phase or spatial and temporal frequency. Many other second-order motion percepts that have been ascribed to a second non-Fourier processing stream can also be explained in the model by interactions between ON and OFF cells within a single, neurobiologically interpreted magnocellular processing stream. Yet other percepts may be traced to interactions between form and motion processing streams, rather than to processing within multiple motion processing streams. The model hereby explains why monkeys with lesions of of the parvocellular layers, but not the magnocellular layers, of the lateral geniculate nucleus (LGN) are capable of detecting the correct direction of second-order motion, why most cells in area MT are sensitive to both first-order and second-order motion, and why after APB injection selectively blocks retinal ON bipolar cells, cortical cells are sensitive only to the motion of a moving bright bar’s trailing edge. Magnocellular LGN cells show relatively transient responses while parvocellular LGN cells show relatively sustained responses. Correspondingly, the model bases its directional estimates on the outputs of model ON and OFF transient cells that are organized in opponent circuits wherein antagonistic rebounds occur in response to stimulus offset. Center-surround interactions convert these ON and OFF outputs into responses of lightening and darkening cells that are sensitive both to direct inputs and to rebound responses in their receptive field centers and surrounds. The total pattern of activity increments and decrements is used by subsequent processing stages (spatially short-range filters, competitive interactions, spatially long-range filters, and directional grouping cells) to determine the perceived direction of motion.

1 Introduction

1.1 First-Order and Second-Order Motion

Apparent motion percepts generated by displays in which nothing actually moves provide important clues to the neural processes that govern motion perception. Most of the old studies of motion perception could be attributed to what Bradick would later call the long-range mechanism. Bradick used random dot kinematograms wherein a rectangular area with horizontal or vertical orientation was displaced from one frame to the next. For appropriate values of spatial displacement and temporal interval between frames (interstimulus interval), subjects observed a clear perception of motion and figure-ground separation. Bradick observed that displacements beyond a quarter of a degree would not provide figure-ground separation. He also observed that orientation was displaced from one frame to the next. For appropriate values of spatial displacement and temporal interval between frames, subjects observed a clear perception of motion and figure-ground separation. Bradick observed that displacements beyond a quarter of a degree would not provide figure-ground separation. He also observed that an increase in the interstimulus interval decreased perceptual segregation. Bradick then suggested that two different processes govern apparent motion: one short-range and the other long-range. A spatial limit, or maximum displacement threshold $D_{\text{max}}$, was proposed over which the short-range process can be activated. $D_{\text{max}}$ was later shown to vary significantly depending on the choice of parameters, such as an increment of the target area, presentation of the target to more peripheral sites, and use of multi-frame kinematograms.

More recently, Bischof and Di Lollo, Cavanagh and Mather, Grossberg and Rudd, and Sperling have argued that the differences in perception obtained for short-range and long-range processes can be more easily attributed to a difference in the stimuli used to test each case, with stimuli classified as first-order or second-order stimuli. A first-order stimulus is a stimulus whose motion can be discriminated by spatially tracking a difference of mean luminance or color over time. In an illustrative second-order motion stimulus, the density of moving dots inside and outside a central square is the same, so there is no difference in luminance between the regions. Second-order motion percepts can discriminate two such areas, even if their mean luminance and color are the same, if they differ in their spatial, temporal, or ocular distribution of mean luminance or color, or when foreground and background vary in their binocular disparity or texture. The motion model developed here correctly detects the perceived direction of motion for a variety of first-order and second-order motion stimuli.

1.2 Fourier and Non-Fourier Motion

Sperling and Chubb and Sperling also distinguished between Fourier and non-Fourier apparent motion stimuli. If the space-time plots of one-dimensional spatial patterns contain oriented intensity contours, then their spatiotemporal signal is said to be Fourier in nature. Fourier stimuli can be detected by linear filters followed by half-wave rectification and standard motion analysis. If the plots do not contain oriented energy, then the stimuli are said to contain non-Fourier motion. They can be detected with nonlinear filters followed by full-wave rectification and standard motion analysis. Chubb and Sperling argued that, for some second-order stimuli, the short-range and long-range mechanisms can produce different results. For example, the perceived direction of motion reverses as the observer moves closer or farther from their $\Gamma$ display, which is a variant of the reverse phi illusion of Anstis and Rogers. In this stimulus, a grating of vertical bars are displaced to the left by an amount equal to 1/4 of the distance between two consecutive bars and the contrast of the bars is reversed. Subjects perceive motion to the left when observing the $\Gamma$ display from nearby (Figure 1a) and motion to the right when observing the $\Gamma$ display from afar (Figure 1b). In both cases, the strength of the perception is considerably weaker when compared to those produced by the first-order and second-order stimuli described above. Chubb and Sperling argued that the far-view motion of $\Gamma$ is detected by the short-range system and can be processed by a first-order
Fourier mechanism, whereas the near-view motion of \( \Gamma \) is detected by a second-order mechanism and requires non-Fourier analysis and full-wave rectification. The model proposed herein utilizes a single processing stream to process both first-order and second-order motion stimuli. The model also suggests that various third-order motion stimuli (e.g., Lu and Sperling 14) are due to a form-motion interaction between two or even three processing streams 15–17.

**FIGURE 1**

The present model analyzes how monocular ON and OFF cells, at an early stage of magnocellular processing, respond through time to luminance increments and decrements before combining their outputs at lightening cells and darkening cells that the present modeling study predicts to exist. These two types of cells, which are predicted to exist early in the motion processing stream, play a role in the model similar to that of simple cells in the form processing stream. The lightening and darkening cells, in turn, input to spatially short-range filters which accumulate evidence for motion in a given direction. The pooled outputs from both lightening and darkening cells in a given direction mimic human percepts of first-order and second-order motion in a variety of conditions. These results are consistent with recent experiments of Gellatly and Blurton 18 showing that the spatiotemporal patterning of luminance increments and decrements through time determines these percepts, rather than distinct types of mechanisms. Our analysis hereby suggests that various second-order properties that have been attributed to a second processing stream are due to interactions between ON and OFF cells within a single processing stream.

2 Neural Substrate of Motion Processing

2.1 Parvocellular and Magnocellular Pathways

Some of the neural data that are clarified by model mechanisms are reviewed in this section and the next. Distinct ON and OFF channels for processing visual information arise at an early stage of retinal organization. Photoreceptors make direct synaptic contacts to the bipolar cells. Some bipolar cells are classified as the ON-center cells that are activated by direct illumination of cones. The OFF-center bipolar cells are inhibited by direct illumination of cones. Responses from the ON bipolar cells project to the ON ganglion cells while the responses from the OFF bipolar cells project to the OFF ganglion cells with amacrine cells mediating antagonistic interactions between the ON and OFF channels.

Enroth-Cugell and Robson 19 found two distinct type of ganglion cells in the cats retina ganglia and classified them into X and Y cells. The X cell small receptive fields (about 3 times smaller than the Y cells) and linear summation of spatial inputs are used in high-acuity vision and the processing of visual form. The Y cell larger receptive fields, nonlinear summation of spatial inputs, and rapidly conducting axons are used to process motion 20. The sustained responses of X cells and the transient responses of Y cells lead to the alternate names sustained and transient cells, respectively 21. In macaque monkeys, ganglion cells have an analogous organization and the two major categories are labeled M and P cells. M cells respond more transiently than P cells to step changes in contrast, and the center of M cell receptive fields has a diameter 2-3 times larger than those of P cells.

Responses from the ganglion cells are projected to the LGN. In primates, the LGN is comprised of 6 layers numbered 1-6 from ventral to dorsal. Cells in the magnocellular layers 1 and 2 are larger, and respond faster and more transiently than cells in the parvocellular layers 3-6. M ganglion cells project mainly to the magnocellular layers of the LGN and to a small portion of superior colliculus 22. Cells at the parvocellular layers receive their inputs from P ganglion cells and respond in a
more sustained way than the cells at magnocellular layers. Livingstone and Hubel have reported
further differences between the magnocellular and parvocellular cells in terms of features like color,
aclty, speed and contrast sensitivity.

Axons from LGN project primarily to layer 4C of cortical area V1. Layer 4C is subdivided in
layers 4Ca and 4Cb. Projections from magnocellular layers of LGN contact layer 4Ca while those
from parvocellular layers of LGN contact layer 4Cb. The segregation between parvocellular and
magnocellular pathways found in LGN is thus maintained in V1.

From layer 4Ca, magnocellular pathways involved in motion perception project to layer 4B,
which then projects to cortical area MT, which is specialized to process visual motion. Cells in MT thus have a predominantly magnocellular visual input. Albright tested direction
and orientation selectivity of V1 and MT cells, observing that virtually all cells in area MT were
directionally selective and responses to first-order moving stimuli were stronger at area MT than
at area V1. Albright showed that nearly all cells (99%) tested at area MT were selective to
first-order motion and 87% of the same cells were also selective to second-order motion.

2.2 Cortical Responses to Motion After Parvocellular or Magnocellular Lesions

Schiller et al. tested the visual capacities of the magnocellular and parvocellular pathways
and their projections. Seven rhesus monkeys were trained to perform visual detection discrimi-
nation tasks. In a control phase of the experiment, the animals were tested for contrast sensitivity,
flicker detection, brightness discrimination, color, texture, pattern discrimination (same stimulus
presented at different spatial frequency), shape perception, stereopsis, and motion. After the control
phase, some monkeys had their parvocellular layers of LGN lesioned while some others had
their magnocellular layers of LGN lesioned. The tests used during the control phase were repeated
to observe the differences in their performance after lesions.

For the motion detection tasks, the monkeys were asked to fixate a point in the center of a
screen. After fixation, a random array of spots filled the screen. In one small region (out of eight
possible regions), the dots moved coherently. Detection was indicated by a direct saccade to the
location of coherent motion. The results showed pronounced degradation in the performance of
monkeys with magnocellular lesions while there was no change in the performance of monkeys with
parvocellular lesions. Motion discrimination was further tested by changing the velocity or the
direction of motion at one of the eight possible locations. Once again, monkeys with magnocellular
lesions showed degradation in their performance. These results suggest that directional selectivity
for continuous motion requires input from magnocellular transient cells, but not from parvocellular
sustained cells.

Some other experiments have used the reversible inactivation of either magnocellular or par-
vocellular layers to examine their contribution to visual responses recorded in other areas of the
visual cortex. In these experiments, inactivation was achieved by injecting either lidocaine
or GABA. Results were quantified using a blocking index to compare responses before and after
blocking: 0 corresponding to no effect and 1 to elimination of cortical response. In area MT, the
blocking index after blocking the magnocellular layers of LGN was 0.75, while after blocking the
parvocellular layers of LGN was 0.11.

Slaughter and Miller showed that injection of 2-amino-4-phosphonobutyrate (APB) pro-
duces prolonged hyperpolarization in retinal ON bipolar cells, making them unresponsive to light
stimulation. Injection of APB had no effect on OFF cells. Schiller tested the effect of APB
injection on the responses of directionally selective motion cortical cells (Figure 2). As a control,
Schiller used a wide bright bar moving on a dark background over the receptive field of a direction-
ally selective cortical cell before APB injection (Figure 3). The cell fired at the passage of both edges of the bar. After APB injection, the same cell fired only at the passage of the trailing edge of the bar. These results suggest that motion of the leading edge of a moving bright bar over a dark background is processed by the ON channel.

FIGURE 2

The model described herein simulates the psychophysical and neural data summarized above. In addition, the model predicts that monkeys with lesions in parvocellular layers, but not magnocellular layers, of the LGN should be able to detect and discriminate the correct direction of motion for second-order stimuli. Before describing the model, it is placed into a larger context by noting how it compares with other relevant motion models in the literature.

FIGURE 3

3 Gradient or Correlational Models of Motion Perception?

Most motion models fall into two categories: gradient models or correlational models. Gradient models detect data collected at single locations and employ a gating operation between a spatially oriented edge detector and a temporal luminance detector. If a cell representing a dark/bright edge (i.e., dark on the left side, bright on the right side) is activated when the temporal unit detects an increment of luminance at the edge location, the gating operation detects that the dark/bright edge is moving leftward (rightward in case of a bright/dark edge). Conversely, if the temporal unit detects a decrement of luminance at the dark/bright edge, the corresponding gating operation detects that the dark/bright edge is moving rightward (leftward in case of a bright/dark edge). Correlational models combine data that are separated both in space and time. In the original Reichardt detector, the delayed response from the left (right) filter is correlated with the response from the right (left) filter, and the output is the difference between these correlated responses.

The Motion Boundary Contour System (motion BCS) model incorporates aspects of both gradient and correlational models; see Figure 4. In the motion BCS, the spatiotemporal visual signal is preprocessed by sustained and transient cells that elaborate properties of gradient models. The sustained cells have oriented receptive fields that generate responses to either dark/light or light/dark oriented stimuli, but not both. The activities of these simple cells are time-averaged and half-wave rectified to generate output signals. The transient cells have unoriented receptive fields that generate transient temporal responses in response to the onset or offset of stimuli, but not both. Their activities are also time-averaged and half-wave rectified to generate output signals. The outputs of these sustained and transient cells are then multiplied, or gated, at each position, as in the gradient models, to derive a local estimate of direction-of-motion. Outputs from gated cells sensitive to the same orientation and direction-of-contrast that lie along a given direction-of-motion are then combined via short-range spatial filters (the analog of Dmax) to accumulate evidence of motion in that direction. This correlational operation results in four types of cells, from all the gated combinations of light/dark or dark/light sustained cells and ON or OFF transient cells. All of these gated cells are sensitive to a particular direction-of-contrast as well as a particular direction-of-motion. A long-range spatial filter then correlates signals again by pooling outputs of gated cells that are sensitive to the same direction-of-motion. Long-range filtering pools signals from both directions-of-contrast, all orientations, and from both eyes. By combining the half-wave rectified output of simple cells that are sensitive to opposite contrast polarities, these
“motion complex cells” carry out a full-wave rectification of the input. A contrast-enhancing competition then selects the cell or cells which receive the largest total inputs. The competition hereby votes for which direction has the most evidence. These competitively-sharpened long-range filter cells are the first true direction-of-motion cells in the model because they combine signals from all previous cell types that are sensitive to a particular direction-of-motion.

**FIGURE 4**

Grossberg and Rudd 10, 51 used this model to simulate many data about short-range and long-range apparent motion, including beta motion, gamma motion, delta motion, split motion, Ternus and reverse-contrast Ternus motion, brief flash speed-up, and aspects of Kortè's laws 52–58. Grossberg and Mingolla 50 extended the model to two-dimensions to simulate how multiple moving orientations could all be pooled into a single direction-of-motion. Francis and Grossberg 16, 59 modeled how a V2 → MT pathway linking form processing in the V1 → V2 cortical stream and motion processing in the V1 → MT cortical stream could be used to provide a complete simulation of Kortè's laws and related data about form-motion interactions 55, 56, 60–64. This motion BCS model has thus been used to simulate a large set of data about short-range and long-range motion perception.

The data of Schiller et al. 34 suggest, however, that the model needs to be refined. This is true because motion perception is spared when oriented sustained cells that are activated by the parvocellular layers of the LGN are blocked by APB. If oriented sustained cells are not needed for effective motion perception, then one needs to explain how processing that is based on the responses of transient cells alone can be used to generate precise estimates of object speed and direction without undermining the other explanations of the model. An initial effort to do this was reported in Nogueira et al. 65. These results were followed by further model development in Chey et al. 66, 67 who simulated how a coherent representation of object direction and speed could be generated by signals contaminated by aperture ambiguities. By using a multiple-scale short-range filter whose larger scales tend to process higher speeds, Chey et al. 66 simulated how speed estimates are influenced by input contrast, duration, dot density, and spatial frequency. Chey et al. 67 showed how the addition of competition, long-range filters, and a directional grouping and attentive priming network can provide a solution to the aperture problem in which unambiguous feature tracking signals capture ambiguous aperture signals and attention can selectively prime a desired direction-of-motion. A schematic of this modified motion BCS is given in Figure 5, which indicates that oriented sustained cells are no longer used.

**FIGURE 5**

The present extension of the motion BCS in Figure 6a elaborates the design of the transient cells and how they activate the short-range filters. A key advance is that contributions from opponent pairs of ON cells and OFF cells are modeled. Antagonistic rebounds, whereby offset of ON (or OFF) cell activity generates a transient onset of OFF (or ON) cell activity, play a central role in simulating data about second-order motion. These direct and rebound ON and OFF responses go through center-surround networks whose outputs are combined at lightening cells and darkening cells. These latter cells play a role much like that of simple cells in the form processing stream, in that they pool input from both ON cells and OFF cells to form responses that are sensitive to a prescribed polarity of change 68–70. The outputs from these lightening and darkening cells then activate short-range filters which pool evidence for motion in a given direction.

Pooling the short-range filter contributions to a given direction from both lightening and darkening cells generates the motion directions that humans perceive in response to first-order and
second-order stimuli under a variety of conditions. These results are simulated in Figures 10-14. More, however, is required of the model. It needs to be consistent with the larger motion BCS theory of Figure 5. In particular, the perceived motion directions need to survive the effects of long-range filtering. For this to happen in all cases, including the case when the display is viewed from afar, it is sufficient to process the lightening and darkening cell outputs according to the same mechanisms in Figure 5 that were originally derived to explain other data, notably data about motion capture and long-range apparent motion; namely, the darkening and darkening cells outputs go through directional short-range filters to accumulate evidence for a given direction before competing across directions and then activating the long-range filters. The results of these simulations are shown in Figures 16-20. The remainder of the article explains in greater detail how these mechanisms generate the simulated percepts.

4 The Proposed Role of Lightening and Darkening Cells

The model will be described in two stages. First the stages through the lightening and darkening cells will be described in order to emphasize their key role in tracking the temporal pattern of luminance increments and decrements. Their outputs are then pooled to show all the simulated effects in the simplest possible framework. Then their outputs will be embedded into the larger motion BCS model to show how all these perceptual emergences in a model that also explains a wide variety of other motion data, including data about global motion capture, motion speed and direction, long-range apparent motion, and directional attentive priming.

Figure 6b shows more mechanistic details of the simpler version of the model that is schematized in Figure 6a. Level 1 of the model represents the visual input as bright or dark signals. These signals are fed to unoriented transient cell filters at Level 2. These filters detect temporal changes in the input and represent them at opponent ON and OFF transient cells. ON (OFF) cells fire at the onset of a bright (dark) stimulus or at the offset of a dark (bright) stimulus.

FIGURE 6

ON and OFF cells input to Level 3 via on-center off-surround kernels where they are organized into lightening and darkening cells. In Figure 6b, lightening cells are represented on the left and darkening cells on the right. Both ON and OFF cells contribute to the activation and deactivation of the lightening and darkening channels so that the segregation between ON and OFF channels is broken. This is in accord with neurophysiological evidence that the ON and OFF systems remain largely segregated up to the lateral geniculate nucleus and then converge in the striate cortex \( \text{38} \). A lightening cell is excited by the ON cells in its center and the OFF cells in its surround and inhibited by the OFF cells in its center and the ON cells in its surround. Similarly, a cell in the darkening channel is excited by the OFF cells in its center and the ON cells in its surround and inhibited by the ON cells in its center and the OFF cells in its surround. For example, the onset a bright spot in the absence of other signals makes a location appear brighter and as a consequence the area in its immediate neighborhood appears darker. This is represented by the cells in lightening channel at the spatial location corresponding to the stimulus center and by the cells in the darkening channel at the spatial locations corresponding to its surround. Therefore, the cells in lightening channel represent a local increase in brightness while the cells in the darkening channel represent a local increase in darkness.

It is important to distinguish the functions of two types of cross-talk in the model; namely, the cross-talk between ON and OFF cells in the lightening and darkening channels at Level 3 and and the cross-talk between the opponent ON and OFF channels at Level 2 (Figure 6b). At the
opponent ON and OFF cells, cross-talk produces an antagonistic rebound of activity in the opposite channel at the offset of a signal. At the lightening and darkening cells, cross-talk permits pooling of opponent signals originating from the surround with the signals at the center. This allows the model to simulate reversed apparent motion from reversed luminance contrast. An illustration of how this is achieved, for example in the Γ display when observed from afar (Figure 1b), is given in Figure 7. A stimuli consisting of two simultaneous bright spots is presented in Frame 1 and switched off in Frame 2 (Figure 7a). The ON cells at the locations of the spots fire during Frame 1. These ON cells then excite the lightening cells at those locations and the darkening cells in their surround. The width of the activity in the darkening channel depends upon the size of the surround. When the spots are switched off, antagonistic rebound transiently turns on the corresponding OFF cells which, in turn, excite the darkening cells at the locations where the bright spots were removed and the lightening cells in their surround.

**FIGURE 7**

Figure 7b, shows the first three Frames of a segment of Γ display when seen from afar. As discussed above, when the bright spots are presented in Frame 1, the ON cells at the locations of the spots fire and in turn activate the lightening cells at those locations and the darkening cells in their surround. In Frame 2, the bright spots are removed and dark spots are presented to their left. The OFF cells in this case fire due to two different kind of processes: first, due to antagonistic rebound at the offset of the bright spots and, second, due to the onset of the dark spots. These OFF cells excite the lightening cells to the right of removed bright spots and to the left of dark spots. The lightening cells to the left of removed bright spots and to the right of dark spots, in addition to the excitatory signals from OFF cells in the surround, also receive inhibitory signals from OFF cells at those locations and therefore remain inactive. Hence, if the Γ display is viewed from a far enough distance, it allows the activities due to offset of bright spots and onset of dark spots to fall close to each other, and the subsequent processing stages of the model time-average and threshold these activities to represent rightward direction-of-motion. Similar arguments apply to the activities of darkening cells and subsequent time frames.

When the Γ display is viewed from nearby (Figure 7c), the lightening (darkening) cell activations due to antagonistic rebound of bright (dark) spots and the onset of dark (bright) spots fall some distance away from each other (how far depends on the size of surround regions of lightening and darkening cells). These activities when time-averaged, thresholded, and pooled by subsequent processing stages represent leftward direction-of-motion.

The outputs from lightening and darkening cells are then fed to their respective short-range spatial filters at Level 4. These spatially averaged activities are thresholded and pooled at Level 5 in the simple version of model in Figure 6b. The mathematical equations of the model are given in Section 5. The reader who wishes to study simulations of model performance first can skip to Sections 6 and 9, where we use the model to simulate neurophysiological data about the effects of anatomical lesions and APB injections on motion processing, and psychophysical data about the reversal of perceived motion direction with distance from the stimulus 12. Sections 10 and 11 discuss other data and models which suggest that various first-order and second-order motion percepts are processed by a single processing stream. In particular, experiments of Lu and Sperling 14, among others, on second-order motion can naturally be explained by the model. The model also indicates at what neurophysiological stages these explanations can be tested by subsequent experiments.
5 Mathematical Description of Model Dynamics

5.1 Level 1: Input Representation

Level 1 of the model registers the input pattern and directs it to the ON and OFF cells of Level 2 (Figure 6b). Let $s_i^+$ represent the response to a bright stimulus and $s_i^-$ to a dark stimulus at the $i^{th}$ location. Then

$$s_i^+ = \begin{cases} 
1.0 & \text{when the bright stimulus is on} \\
0.0 & \text{otherwise}
\end{cases} \quad (1)$$

and

$$s_i^- = \begin{cases} 
1.0 & \text{when the dark stimulus is on} \\
0.0 & \text{otherwise}
\end{cases} \quad (2)$$

5.2 Level 2: Unoriented Transient Filter

Level 2 detects temporal changes in the input signal via ON and OFF unoriented transient cells. ON (OFF) cells fire either at the onset of an increase (decrease) in luminance or, via antagonistic rebound, at the offset of a decrease (increase) in luminance. A gated dipole circuit is used to represent these opponent transient changes. Such a circuit has previously been used to model transient responses to visual cues under a variety of conditions. In both the ON and OFF channels, chemical transmitters gate signals in their pathways in such a way as to attempt to maintain unbiased transduction. Their slow rates of habituation and recovery determines antagonistic rebounds in the circuit.

Figure 8 illustrates the functioning of such a gated dipole circuit. Initially, when no phasic inputs are present, both channels receive equal tonic arousal signals $\gamma_u$. Therefore, activities $u_1$ and $u_2$ are equal. They cancel each other due to opponent interaction and both channels remain subthreshold. When a phasic input, $s_i^+$, due to presentation of bright stimulus is turned on, $u_1$ receives both tonic and phasic inputs. Activity $u_1$ gets larger than activity $u_2$ and neurotransmitter $v_1$ habituates, or inactivates, slowly. Since $u_1$ responds faster than $v_1$, initially $v_3$ becomes larger than $u_4$ and $u_5$ starts firing above threshold, resulting in $u^{ON}$ signal. When neurotransmitter $v_1$ is sufficiently habituated, $u^{ON}$ becomes subthreshold although the stimulus remains on. When the bright stimulus is removed, $u_4$ and $u_2$ receive only tonic input. Since neurotransmitter $v_1$ was inactivated during presentation of the bright stimulus $s_i^+$, its value is now less than that of the neurotransmitter $v_2$. Therefore $u_4$ becomes larger than $u_5$. This results in a positive response at $u_6$ and an OFF response $u^{OFF}$ is generated via an antagonistic rebound. Signal $u^{OFF}$ becomes zero after $v_1$ accumulates back to its equilibrium value. Similar arguments apply for the onset of a dark stimulus. In summary, an ON cell fires at the onset of a bright stimulus and at the offset of a dark stimulus, whereas an OFF cell fires at the offset of a bright stimulus and the onset of a dark stimulus.

**FIGURE 8**

The ON-channel of the dipole responds to a net increase $s_i^+$ in the luminance, as in (1), while the OFF-channel responds to a net decrease $s_i^-$, as in (2):

**ON-Channel Input Stage**

Let

$$\frac{d}{dt}u_{1i} = -A_2u_{1i} + s_i^+ + \gamma_u, \quad (3)$$
where \( u_{1i} \) is the activity of the ON channel, \( s_i^+ \) is the signal from Level 1 as described in (1), and \( \gamma_u \) is a tonic arousal level.

**Off-Channel Input Stage**

Let

\[
\frac{d}{dt} u_{2i} = -A_2 u_{2i} + s_i^- + \gamma_u, \tag{4}
\]

where \( u_{2i} \) and \( s_i^- \) have analogous definitions and \( \gamma_u \) is the same arousal level as in (3).

**ON-Transmitter Transmitter Production-Inactivation**

Let \( v_{1i} \) be the habituation transmitter that multiplies, or gates, the half-wave rectified signal \([u_{1i}]^+\) in the ON channel. Transmitter \( v_{1i} \) varies more slowly than \( u_{1i} \) via the equation:

\[
\frac{d}{dt} v_{1i} = B_2 (1 - v_{1i}) - C_2 [u_{1i}]^+ v_{1i}, \tag{5}
\]

where \([w]^+ = \max(w,0)\) denotes half-wave rectification.

**OFF-Transmitter Transmitter Production-Inactivation**

Similarly, the slowly varying habituation transmitter \( v_{2i} \) in the OFF channel gates the OFF channel signal \([u_{2i}]^+\) via the equation:

\[
\frac{d}{dt} v_{2i} = B_2 (1 - v_{2i}) - C_2 [u_{2i}]^+ v_{2i}, \tag{6}
\]

Equations (5) and (6) control the level of available neurotransmitter. An increase in signal \( u_{ij} \) increases the inactivation and release of transmitter via the mass action term \(-C_2 [u_{ij}]^+ v_{ij}\). Transmitter accumulates to the maximum value of 1.0 via term \(B_2 (1 - v_{ij})\) at rate \(B_2\).

**Transmitter-Gated ON-Activation**

The transmitter-gated signal \( u_{1i}^- v_{1i} \) activates the next stage of ON channel processing:

\[
\frac{d}{dt} u_{3i} = -A_2 u_{3i} + D_2 [u_{1i}]^+ v_{1i}. \tag{7}
\]

**Transmitter-Gated OFF-Activation**

The same thing happens in the OFF channel:

\[
\frac{d}{dt} u_{4i} = -A_2 u_{4i} + D_2 [u_{2i}]^+ v_{2i}. \tag{8}
\]

**Normalized Opponent ON-Activation**

Competition between the ON and OFF channels determines the opponent ON and OFF activations:

\[
\frac{d}{dt} u_{5i} = -A_2 u_{5i} + (E_2 - u_{5i}) u_{3i} - (F_2 + u_{5i}) u_{4i}. \tag{9}
\]

**Normalized Opponent OFF-Activation**

Similarly,

\[
\frac{d}{dt} u_{6i} = -A_2 u_{6i} + (E_2 - u_{6i}) u_{4i} - (F_2 + u_{6i}) u_{3i}, \tag{10}
\]

where \(A_2\) is the passive decay rate, and \(E_2\) and \(F_2\) are the upper and lower bounds of ON and OFF cell activation.

**ON Output:**
These output are then thresholded and rectified. This forms the input for Level 3.

\[ u_i^{ON} = [u_{5i} - \Gamma_u]^+ . \]  

**OFF Output:**

Similarly,

\[ u_i^{OFF} = [u_{6i} - \Gamma_u]^+ . \]  

### 5.3 Level 3: Lightening and Darkening Channels

Two center-surround networks process the ON and OFF outputs from Level 2. This operation spatially contrast enhances the ON and OFF output signals. Let \( w_i^L \) and \( w_i^D \) represent the activity of a cell at the \( i^{th} \) position in the lightening and darkening channels, respectively.

**Lightening Channel**

\[
\frac{dw_i^L}{dt} = -A_3 w_i^L + (B_3 - w_i^L) \left[ \sum_j G_{ji}u_j^{ON} + \sum_j H_{ji}u_j^{OFF} \right] \\
- (C_3 + w_i^D) \left[ \sum_j H_{ji}u_j^{OFF} + \sum_j G_{ji}u_j^{ON} \right].
\]  

**Darkening Channel**

\[
\frac{dw_i^D}{dt} = -A_3 w_i^D + (B_3 - w_i^D) \left[ \sum_j G_{ji}u_j^{OFF} + \sum_j H_{ji}u_j^{ON} \right] \\
- (C_3 + w_i^D) \left[ \sum_j H_{ji}u_j^{ON} + \sum_j G_{ji}u_j^{OFF} \right],
\]

where \( G_{ji} \) and \( H_{ji} \) are the Gaussian center and surround kernels with parameter \( \alpha_{we} \) controlling their amplitude and parameters \( \sigma_c \) and \( \sigma_s \) controlling their sizes:

\[
G_{ji} = \frac{\alpha_{we}}{\sigma_c \sqrt{2\pi}} \exp\left[\frac{-(j-i)^2}{2\sigma_c^2}\right],
\]

\[
H_{ji} = \frac{\alpha_{we}}{\sigma_s \sqrt{2\pi}} \exp\left[\frac{-(j-i)^2}{2\sigma_s^2}\right].
\]

Equations (13) and (14) are shunting center-surround equations. The first term \(-A_3 w_i^L\) controls passive decay. The second term, \((B_3 - w_i^L)[\sum_j G_{ji}u_j^{ON} + \sum_j H_{ji}u_j^{OFF}]\), in (15) describes the excitatory signals from the ON cells in the center \((\sum_j G_{ji}u_j^{ON})\) and the OFF cells in the surround \((\sum_j H_{ji}u_j^{OFF})\); that is, bright stimuli in the center or dark stimuli in the surround excite the lightening channel. Term \((B_3 - w_i^L)\) is a shunting term which sets the maximum possible activity of \( w_i^L \) at \( B_3 \). The last term, \((C_3 + w_i^D)[\sum_j H_{ji}u_j^{OFF} + \sum_j G_{ji}u_j^{ON}]\), in (15) describes the inhibitory signals from the ON cells in the surround \((\sum_j H_{ji}u_j^{OFF})\) and the OFF cells in the center \((\sum_j G_{ji}u_j^{ON})\); that is, dark stimuli in the center and bright stimuli in surround inhibit the lightening channel. The shunting term \((C_3 + w_i^D)\) sets the minimum activity of \( w_i^L \) at \(-C_3\). Similarly,
the second term, \((B_3 - w^D_i)[\sum_j G_{ji}w^\text{OFF}_j + \sum_j H_{ji}w^\text{ON}_j]\), in (16) is the excitatory signal from the OFF cells in the center (\(\sum_j G_{ji}w^\text{OFF}_j\)) and the ON cells in the surround (\(\sum_j H_{ji}w^\text{ON}_j\)); that is, dark stimuli in the center or bright stimuli in the surround excite the darkening channel. Term \((C_3 + w^D_i)[\sum_j H_{ji}w^\text{OFF}_j + \sum_j G_{ji}w^\text{ON}_j]\) describes the inhibitory signals from the ON cells in the center (\(\sum_j H_{ji}w^\text{OFF}_j\)) and the OFF cells in the surround (\(\sum_j G_{ji}w^\text{ON}_j\)); that is, bright stimuli in the center or dark stimuli in the surround inhibit the darkening channel.

### 5.4 Level 4: Short-Range Spatial Filtering

The next operation pools the activations of cells that are spatially close by means of a short-range spatial filter. A separate filter is used for the lightening and darkening channels. A Gaussian kernel \(P_{ji}\) ensures that the contributions from adjacent neighbors are larger than the contributions from more distant neighbors. Let \(y^L_i\) and \(y^D_i\) denote the activity of the \(i\)th filter in lightening and darkening channels, respectively.

**Lightening Channel**

\[
\frac{dy^L_i}{dt} = -A_4 y^L_i + (B_4 - y^L_i) \sum_j P_{ji} [w^L_j]^+. \tag{17}
\]

**Darkening Channel**

\[
\frac{dy^D_i}{dt} = -A_4 y^D_i + (B_4 - y^D_i) \sum_j P_{ji} [w^D_j]^+. \tag{18}
\]

The Gaussian kernel \(P_{ji}\) is defined by:

\[
P_{ji} = \frac{\alpha_y}{\sigma_y \sqrt{2\pi}} \exp \left[ -\frac{(j-i)^2}{2\sigma_y^2} \right]. \tag{19}
\]

For simplicity, the Gaussian spatial filter is chosen to be of a single-scale and isotropic. This is sufficient for the cases where the stimuli generate motion in one dimension. Time-averaging followed by thresholding arranges data in the direction-of-motion. Multiscale short-range anisotropic spatial filters that accumulate evidence for motion in a particular direction are essential for a two-dimensional motion grouping system to detect object speed and direction.

### 5.5 Level 5: Lightening-Darkening Pooling

The thresholded outputs from the short-range spatial filter are combined at Level 5. Let \(z_i\) be the activity of the \(i\)th node. Then

\[
z_i = [y^L_i - \Gamma_y]^+ + [y^D_i - \Gamma_y]^+ \tag{20}
\]

The cells \(z_i\) at Level 5 are sensitive to direction-of-motion and insensitive to direction-of-contrast as in the Grossberg-Rudd model and its subsequent elaborations.

### 6 Model Simulations

#### 6.1 Simulation Parameters and Layout

The model was used to simulate examples of first-order motion, first-order motion after blocking of ON cells, second-order motion, and \(\Gamma\) display second-order motion as seen from near and far. The parameters for all simulations were: \(A_2 = 10.0, B_2 = 0.05, C_2 = 5.0, D_2 = 200.0, E_2 = 5000.0, F_2 = \ldots\)
6.2 Simulation of Antagonistic Rebound

Before discussing simulations using space-time plots, we clarify how antagonistic rebounds look by describing two simulations of a Level 2 cell's transient ON and OFF responses: (1) a stimulus is presented and switched off; (2) it is replaced by a stimulus of opposite contrast when it is switched off. Figure 9a shows the results for the first case. Since ON and OFF channels are symmetric, presentation of a bright ($s^B_i$) or a dark stimulus ($s^D_i$) yields the same result in their respective channels. The time sequence of stimulus presentation is shown at the bottom of the plot. The ON and OFF transients have approximately the same maximum level of activation in this case. Figure 9b shows the results of the second case in which a stimulus is replaced by the stimulus of opposite contrast. In this case the OFF (ON) response for a bright (dark) stimulus is larger. In our simulation examples discussed next, the second situation is applicable only in case of second-order motion stimulus when bright locations are replaced by dark locations and vice versa. In all other cases, the bright and dark locations are simply switched off.

Figure 9

6.3 Simulation of First-Order Motion

A simple example of a first-order stimulus is a bright bar sliding horizontally. Figure 10a shows the spatiotemporal representation of cross-section of a bright bar sliding horizontally to the right over a grey background. The bright bar is 30 units wide and covers nodes 11-40 at Frame 1. Starting at Frame 2, the bar moves to the right at a speed of 5 units per frame.

Figure 10

Figure 10b shows the ON cell activity ($v_i^{ON}$) and Figure 10c the OFF cell activity ($v_i^{OFF}$). Figure 10d shows the response at the lightening channel ($w_i^L$) and Figure 10e at the darkening channel ($w_i^D$) of Level 3. Figures 10f and 10g show the thresholded rectified responses of the short-range spatial filter (Level 4) for the lightening ($[y_i^L - \Gamma^L]_+$) and darkening ($[y_i^D - \Gamma^D]_+$) channels, respectively. Figure 10h shows the pooled response ($z_i$) at Level 5. The result shows that the model is sensitive to the motion of both edges of the bright sliding bar. Since the model is based on transient cell responses alone, it agrees with the findings of Schiller et al. that the magnocellular pathways are sufficient to detect and discriminate first-order continuous motion.

6.4 Simulation of First-Order Motion With Blocked ON Cells

APB injections block the responses of ON bipolar cells without affecting the responses of OFF cells. In the model, the outputs of ON and OFF channels are independent of each other. This clarifies...
how selective blocking of either channel alone can occur without affecting the other. Schiller found that blocking ON bipolar cells using APB makes direction-selective cortical cells in monkeys insensitive to the leading edge of a moving bright bar.

Blocking the output from the ON channel of Level 2 was achieved by raising the threshold \( \Gamma_2 \) in \((13)\) such that the responses \( u^{ON}_i \) were always zero. The stimulus used was the moving bright bar of the first-order simulation described in Figure 11a. Figure 11b shows the ON cell activity \( u^{ON}_i \) and Figure 11c the OFF cell activity \( u^{OFF}_i \). The responses at the lightening channel \( w^L_i \) and the darkening channel \( w^D_i \) of Level 3 are shown in Figures 11d and 11e, respectively. No activity is present at the onset of the bar in Frame 1 or at the locations of the leading edge in both channels. Figures 12f and 12g show the thresholded rectified responses of the short-range spatial filter (Level 4) for the lightening \( (y^L_i - \Gamma_y)^+ \) and darkening \( (y^D_i - \Gamma_y)^+ \) channels, respectively. Figure 11h shows the pooled response \( z_i \) at Level 5. The results show that the model is insensitive to the leading edge of the moving bright bar when the ON channel is blocked. The model predicts that blocking the OFF bipolar cells would make direction-selective cortical cells insensitive to the trailing edge. Moreover, if a dark moving bar was used instead of a bright bar, then blocking ON (OFF) cells should make the system insensitive to the trailing (leading) edge.

**FIGURE 11**

**6.5 Simulation of Second-Order Motion**

A contrast-reversing noise field was used as an example of second-order motion. Figure 12a shows spatiotemporal plot of this stimulus. A random pattern of ten contiguous bright and dark bars (10 units wide) is presented at Frame 1. Starting at Frame 2, these bars reverse their contrast one bar per frame from left to right. A motion to the right is observed.

**FIGURE 12**

Figure 12b shows the ON cell activity \( u^{ON}_i \) and Figure 12c the OFF cell activity \( u^{OFF}_i \). Figures 12d and 12e show the responses at the lightening channel \( w^L_i \) and the darkening channel \( w^D_i \) of Level 3, respectively. Figures 12f and 12g show the thresholded rectified responses of the short-range spatial filter (Level 4) for lightening \( (y^L_i - \Gamma_y)^+ \) and darkening \( (y^D_i - \Gamma_y)^+ \) channels, respectively. At the start of the experiment at Frame 1, a motion signal is seen at the bright locations in the lightening channel and the dark locations in the darkening channel. When a bar switches from bright to dark, its transient response is captured at the location of the bar in the lightening channel and in its surround in the darkening channel, and vice versa. These responses are pooled at Level 5, as shown in Figure 12h. This output tracks the motion from left to right. The model also predicts that, as in first-order motion, macaque monkeys with lesions in the parvocellular layers of LGN should be able to detect second-order motion. This was not tested by Schiller et al.

Harris and Smith also used this stimulus to test if it would evoke optokinetic nystagmus (OKN) in an attempt to localize the site of detection of second-order motion. They found that, although the detection of correct direction of motion in this case was strong, it did not evoke OKN. As the first-order stimuli evoke OKN they concluded that the first-order and second-order stimuli are processed by two different channels. Our simulation results of this experiment suggest that the signal for OKN is perhaps tapped before the long-range filtering stage. For example, for first-order stimuli, the signals before the long-range filter stage already show correct directional preference (Figures 10f and 10g), whereas for second-order stimulus the signals are still ambiguous (Figures 12f and 12g). This ambiguity is resolved in the model at the long-range filter stage (Figure 12h).
This hypothesis about the possible site for signaling OKN is consistent with recent data showing that vergence eye movements are also processed at an early stage of visual processing. For example, Masson et al. used anticorrelated dense patterns to show that vergence eye movements derive their visual inputs from an early cortical processing stage. For example, they reported that: “These data indicate that the vergence eye movements initiated at ultrashort latencies result solely from locally matched binocular features, and derive their visual input from an early stage of cortical processing before the level at which depth percepts are elaborated” (p 283). The long-range filter stage in the model is proposed to occur in cortical area MT, which is the model site at which motion depth percepts are elaborated. It may thus be that several types of signals for the control of eye movements derive their visual inputs from processing stages earlier than those at which depth percepts are elaborated.

6.6 Simulation of \( \Gamma \) Display Motion - Near View

Figure 13a shows the spatiotemporal layout of the \( \Gamma \) display when seen from nearby. A grating of bars, each 20 units wide, shifts to the left by 1/4 spatial distance between two consecutive bars. Therefore, the distance between two bars equals 80 units. Figure 13b shows the ON cell activity \( w_{ON} \) and Figure 13c the OFF cell activity \( w_{OFF} \). Figures 13d and 13e show the responses at the lightening channel \( w_{L} \) and the darkening channel \( w_{D} \) of Level 3, respectively. Figures 13f and 13g show the thresholded rectified responses of the short-range spatial filter (Level 4) for lightening \( (y^L - \Gamma y)^+ \) and darkening \( (y^D - \Gamma y)^+ \) channels, respectively. Figure 13h shows the pooled response \( (z_i) \) at Level 5. The output tracks motion to the left; i.e., in the direction of the motion of the grating.

FIGURE 13

6.7 Simulation of \( \Gamma \) Display Motion - Far View

Figure 14a shows the spatiotemporal plot of the \( \Gamma \) display as seen from afar. The display is shrunk 4 times relative to the display when seen from nearby. Each segment of the grating (dark or bright) is therefore 5 units wide and the distance between the centers of the two consecutive segments now equals 20 units. Figure 14b shows the ON cell activity \( w_{ON} \) and Figure 14c the OFF cell activity \( w_{OFF} \). Figures 14d and 14e show the response at lightening channel \( w_{L} \) and darkening channel \( w_{D} \) of Level 3, respectively. Although the grating is shifting to the left, the cells at this stage already begin to prefer the rightward direction of motion. This is due to the cross-talk between ON and OFF cells as described in Section 4. Figures 14f and 14g show the thresholded rectified responses of the short-range spatial filter (Level 4) for lightening \( (y^L - \Gamma y)^+ \) and darkening \( (y^D - \Gamma y)^+ \) channels, respectively. Since the activities due to off-surrund contributions in a channel now fall within the effective bandwidth of the Gaussian short-range filter, their average over time is now organized to become sensitive to the rightward direction of motion and is further contrast-enhanced by thresholding. Figure 14h shows the pooled response \( (z_i) \) at Level 5. The output detects the motion to the right which is in the opposite direction of the motion of the grating.

FIGURE 14

7 Additional Motion BCS Model Mechanisms

The results in Figures 10-14 highlighted the role of lightening and darkening cells. We now embed these cells in the full motion BCS model of Figure 5 to show how they give rise to directionally
sensitive motion output cells. When the opponent ON and OFF channels and the lightening and darkening cells of Figure 6a are embedded within the more comprehensive motion BCS model, all of the above percepts can again be simulated despite the smoothing effects of the long-range filter. The long-range filter is the stage at which contributions from lightening and darkening cells are finally pooled. These long-range filter cells are also the ones at which sensitivity to direction-of-motion and insensitivity to direction-of-contrast is finally achieved by pooling signals of opposite contrast polarity. Before that stage is reached, the undirectional transient cell responses are progressively transformed into directional cells that are capable of using unambiguous feature tracking motion signals to capture ambiguous motion signals that arise due to the aperture problem and to thereby generate global representations of an object’s speed and direction.

The relevant processing stages are as follows.

An early stage in the transformation of undirectional transient responses uses an inhibitory veto mechanism. Barlow and Levick first showed that inhibition was crucially involved in the function of directionally selective ganglion cells in the rabbit retina. They concluded that the directional selectivity of these cells was brought about through inhibitory lateral connections, probably mediated by retinal horizontal cells. These directionally-specific inhibitory connections veto responses in nearby cells, implementing a kind of logical NOT operation. The ganglion cells responded to single light flashes with much the same threshold as paired flashes presented in the direction that was not vetoed by inhibition. Gamma-aminobutyric acid (GABA) mediates inhibition in directional rabbit retina cells. Introduction of a GABA antagonist into the rabbit retina eliminates the selectivity of the previously directionally selective cells, causing them to respond equally well to both directions of movement.

Evidence for inhibitory processes involved in directional selectivity has also been found in cat cortical cells. Hubel and Wiesel suggested that directional selectivity of simple cells could be explained by summation of responses from adjacent ON and OFF regions of the cell, where an ON region responded to the luminance increment and an OFF region responded to a luminance decrement. Such ON and OFF responses have been demonstrated in two classes of retinal ganglion cells that converge at the simple cells in cortex. However, a number of studies have later rejected the hypothesis that the temporal coincidence of these ON and OFF responses can explain directional selectivity. For example, Goodwin et al. studied simple cells in cat striate cortex which showed ON and OFF receptive field regions for both stationary flashed stimuli and moving edges. The majority of these cells could not be correlated with the spatial arrangement of their receptive fields and were independent of the width of the moving bar used as a stimulus, invalidating the spatial summation hypothesis. Like Barlow and Levick, they concluded that inhibition in the non-preferred direction was primarily responsible for the direction selectivity.

Both Barlow and Levick and Goodwin et al. found directional selectivity to be contained within small sub-units of observed cell receptive fields. For example, Goodwin et al. reported that one cell was divided into 22 sub-units, each of which demonstrated the same directional selectivity of the cell as a whole. In fact, Goodwin et al. were unable to find non-directionally-selective subregions within the receptive field down to a displacement threshold of 1 minute of arc.

In summary, early directional selectivity appears to be based on inhibitory veto processing, as opposed to facilitatory or correlational operations. These processes seem to operate at a small scale in comparison to the size of individual receptive fields of directionally selective cells in either rabbit retina or cat cortical cells.

At what processing stage does such a directional veto mechanism operate? Chey et al. suggested why it occurs as part of transient cell processing prior to the short-range filter. It can here set up local directional estimates at directional transient cells before evidence for these estimates is spatially accumulated across a moving trajectory by directionally-sensitive short-range filter cells.
We suggest herein that these directional transient cells operate upon the outputs of the lightening and darkening channels before the outputs are, in turn, processed by the short-range filters.

Competition across direction within each channel then acts to enhance the outputs of directional short-range filter cells that have few directional competitors at a given position, while attenuating outputs of directional cells with many directional competitors, without disrupting speed estimates. A divisive, or shunting, competition across direction and scale accomplishes this by computing the ratio of competing activities \[^{90,91}\]. Unambiguous feature tracking signals are hereby boosted relative to ambiguous signals, and ambiguous signals are biased towards a direction of motion that is perpendicular to a line's orientation.

The long-range motion filter then pools signals from multiple orientations and contrast polarities in a prescribed direction-of-motion. It is the model processing stage that generates cells that are truly direction selective, and is proposed to occur in cortical area MT where cells with similar receptive field properties have been reported \(^{25,31,92,93}\). This processing stage also pools signals from both eyes \(^{51}\). It hereby achieves the depth selectivity of MT cells \(^{94,95}\) and helps to explain how long-range apparent motion can occur with dichoptically presented stimuli \(^{96,97}\).

The directional grouping and attentional priming stage of Figure 5 was not simulated because its role is not important in processing the displays that are being simulated. Extensive simulations showed that the ordering of directional transient cells, competition, and short-range filtering could be varied without disrupting the main qualitative results. They are quite robust.

8 Mathematical Description of the Motion BCS

Equations (1) - (16) above, through the lightening and darkening cells, are the same as before. The subsequent processing stages, summarized in Figure 15, are defined as follows. Directional transient cells are derived through the intervention of directional interneurons \(^{67}\).

**FIGURE 15**

Directional Interneurons

Directional interneuron activity $\xi^v_i$ time-averages the lightening (or darkening) cell output:

$$\frac{d\xi^v_i}{dt} = -\xi^v_i + [w^v_i - \Gamma^w]^+,$$

where $v = L$ for lightening and $v = D$ for darkening.

Directional Transient Cells - Left Direction

The directional transient cell activity $x_i^{vl}$ that prefers left direction-of-motion receives excitatory input from the lightening (or darkening) cell which is vetoed by the directional interneuron activity offset by one unit in the left direction:

$$\frac{dx_i^{vl}}{dt} = -A_5 x_i^{vl} + B_5 [w^v_i - \Gamma^w]^+ - C_5 [\xi^v_{i-1}]^+,$$

Directional Transient Cells - Right Direction

Similarly, the directional transient cell activity $x_i^{vr}$ that prefers right direction-of-motion receives excitatory input from the lightening (or darkening) cell which is vetoed by the directional interneuron activity offset by one unit in the right direction:

$$\frac{dx_i^{vr}}{dt} = -A_5 x_i^{vr} + B_5 [w^v_i - \Gamma^w]^+ - C_5 [\xi^v_{i+1}]^+.$$
Short-Range Spatial Filters

Short-range spatial filter activity $y_{i}^{\nu\nu}$ performs space and time averaging of directional cell responses. A Gaussian kernel $P_{ji}$ ensures that the contributions from adjacent neighbors are larger than the contributions from more distant neighbors:

$$\frac{dy_{i}^{\nu\nu}}{dt} = -A_{\nu}y_{i}^{\nu\nu} + (B_{\nu} - y_{i}^{\nu\nu}) \sum_{j} P_{ji}[x_{j}^{\nu\nu}]^+, \quad (24)$$

and

$$P_{ji} = \frac{\alpha_{\nu}}{\sigma_{\nu} \sqrt{2\pi}} \exp \left[ -\frac{(j - i)^2}{2\sigma_{\nu}^2} \right], \quad (25)$$

where $\nu\nu = LL$ for lightening-left, $\nu\nu = DL$ for darkening-left, $\nu\nu = LR$ for lightening-right, and $\nu\nu = DR$ for darkening-right. These activities are half-wave rectified to generate output signals

$$Y_{i}^{\nu\nu} = [y_{i}^{\nu\nu} - Y_{y}]^+. \quad (26)$$

Directional Competition

Competition occurs between left and right directional cells that obey membrane equations. This competition computes the ratio of competing activities in lightening and darkening channels. For simplicity, it is assumed that the competition acts quickly. Its activities are thus computed at steady state and half-wave rectified to yield the output signals:

$$\Upsilon_{i}^{LL} = \frac{[Y_{i}^{LL} - Y_{i}^{LR}]^+}{\beta_{\nu} + Y_{i}^{LL} + Y_{i}^{LR}} \quad (27)$$

$$\Upsilon_{i}^{DL} = \frac{[Y_{i}^{DL} - Y_{i}^{DR}]^+}{\beta_{\nu} + Y_{i}^{DL} + Y_{i}^{DR}} \quad (28)$$

$$\Upsilon_{i}^{LR} = \frac{[Y_{i}^{LR} - Y_{i}^{LL}]^+}{\beta_{\nu} + Y_{i}^{LL} + Y_{i}^{LR}} \quad (29)$$

and

$$\Upsilon_{i}^{DR} = \frac{[Y_{i}^{DR} - Y_{i}^{DL}]^+}{\beta_{\nu} + Y_{i}^{DL} + Y_{i}^{DR}} \quad (30)$$

Long-Range Spatial Filters

Long-range spatial filter activity $z_{i}^{\nu}$ separately pools the outputs from the lightening and darkening channels in both the left and right directions. A Gaussian kernel $q_{ji}$ ensures that the contributions from adjacent neighbors are larger than the contributions from more distant neighbors, as in:

$$\frac{dz_{i}^{\nu}}{dt} = -A_{\nu}z_{i}^{\nu} + (B_{\nu} - z_{i}^{\nu}) \sum_{j} q_{ji} (\Upsilon_{j}^{L\nu} + \Upsilon_{j}^{D\nu}), \quad (31)$$

where $\nu = L$ for left, $\nu = R$ for right, and

$$q_{ji} = \frac{\alpha_{\nu}}{\sigma_{\nu} \sqrt{2\pi}} \exp \left[ -\frac{(j - i)^2}{2\sigma_{\nu}^2} \right]. \quad (32)$$
The output is thresholded at \( \Gamma_z \) and half-wave rectified to generate output signals

\[
Z_i^r = [z_i^r - \Gamma_z]^+.
\]

9 Motion BCS Simulations

The same stimuli as in Figures 10-14 are now simulated in Figures 16-20. The effects of each processing stage are shown here. The simulation parameters for earlier stages were as before and for motion BCS were: \( A_5 = 10.0, B_5 = 10.0, C_5 = 50.0, \Gamma_w = 0.1, A_6 = 1.0, B_6 = 1.0, \alpha_y = 15.0, \sigma_y = 1.5, \Gamma_y = 0.1, \beta_y = 0.0001, A_7 = 1.0, B_7 = 1.0, \alpha_z = 15.0, \sigma_z = 5.0 \) and \( \Gamma_z = 0.6 \). In Figures 16-20, activities of left and right directional transient cells for the lightening channel \( (x_i^{LL} \text{ and } x_i^{LR}) \) are shown in (a) and (b), respectively, and for the darkening channel \( (x_i^{DL} \text{ and } x_i^{DR}) \) in (c) and (d). The left and right short-range filters for the lightening channel \( (y_i^{LL} \text{ and } y_i^{LR}) \) are shown in (e) and (f), respectively, and for the darkening cells \( (y_i^{DL} \text{ and } y_i^{DR}) \) in (g) and (h). The pooled activity of left direction cells after competition \( (\eta_i^{LL} + \eta_i^{DL}) \) is plotted in (i) and right direction \( (\eta_i^{LR} + \eta_i^{DR}) \) in (j). The left and right long-range filter output \( (Z_i^L \text{ and } Z_i^R) \) are plotted in (k) and (l), respectively. The main thing to note is whether energy is concentrated in the output of the left, \( Z_i^L \), or right, \( Z_i^R \), long-range filter.

FIGURES 16 - 20

10 A Single Processing Stream for First-Order and Second-Order Motion?

A number of researchers have suggested that first-order and second-order motion stimuli are processed by independent pathways. The psychophysical evidence for these arguments include scale-dependent direction of motion reversal in the \( \Gamma \) display \(^{12}\), first-order and second-order motion percepts in a multi-frame motion sequence \(^{98, 99}\), different temporal sensitivities for first-order and second-order motion stimuli \(^{100-105}\), first-order but not second-order motion detection at the absolute detection threshold \(^{105, 106}\), first-order but not second-order motion activation of the optokinetic eye movement system \(^{78}\), and a small phase-dependence during direction judgment experiments on superimposed Fourier and non-Fourier stimuli \(^{14}\). Nevertheless, psychophysical experiments on adaptation and sensitivity studies provide evidence that first-order and second-order stimuli are processed by single processing stream \(^{107-109}\). Taub et al. \(^{110}\) have conducted experiments with varying degrees of nonlinearity in non-Fourier motion stimuli and compared velocity discrimination judgments for first-order and second-order stimuli. Their findings are consistent with a single processing stream.

There is also neurophysiological evidence in support of single processing stream. Albright \(^{33}\) found that 87% of the cells in area MT that respond to the first-order stimuli also respond to the second-order stimuli. The model proposed herein utilizes a single processing stream to process both first-order and second-order motion stimuli. The model hereby clarifies why cells in area MT can respond to both first-order and second-order motion stimuli \(^{33}\). In particular, both first-order and second-order motion stimuli are processed monocularly \(^{14}\), whereas cells in MT are already binocularly sensitive. The model mechanisms that process these stimuli occur prior to the binocular fusion of information that is proposed to occur at a long-range spatial filter that converges on model MT cells.
Johnston and Clifford have convincingly argued that a single processing stream is sufficient to simulate a number of motion percepts that others have used to argue for multiple processing channels. Their model is based upon formal Taylor series expansions of image brightness around a point of interest. These expansions are used in conjunction with integral operations to provide “a least squares estimate of image speed based on measures of how the image brightness and its derivatives are changing with respect to space and time” (p 1123). The present approach directly develops a neural model of the magnocellular brain mechanisms that subserve motion perception. It is not yet clear how the two approaches can be linked.

The Motion BCS model that is developed herein has shown that various second-order properties that have been attributed to a second processing stream may be due to interactions between ON and OFF cells within a single processing stream. We wish to emphasize the logical force of this demonstration. It suggests that various earlier arguments about the existence of different first-order and second-order streams are logical nonsequitors. Different motion properties do not imply different motion processes. Given that our analysis is also linked to known thalamocortical ON and OFF cell properties, which have not been incorporated into earlier models, the question of whether separate processing streams process first-order and second-order motion needs to be approached with renewed caution.

To make these demonstrations, the present study proposes a model of lightening and darkening cells and refines the first few processing stages of a neural architecture, called the Motion BCS, that has previously been used to simulate many other data about visual motion perception. For example, by the time signals in the motion BCS are processed by the short-range filters, they can do pre-attentive feature tracking. Subsequent stages of the motion BCS model include a long-range spatial filter at which multiple orientations, contrast polarities and inputs from both eyes converge to achieve true directionally selective cells. These cells feed on attentive directional grouping stage that uses the directional feature tracking signals to achieve global motion capture and attentive grouping of motion signals. These attentive mechanisms were not needed to simulate the data considered herein.

We wish to emphasize that, although only one motion processing stream is needed to explain the first-order and second-order motion percepts that are analyzed herein, these results are not meant to imply that multiple processing streams do not operate in other situations, or that interactions between these streams cannot influence motion percepts. On the other hand, these other processing streams are often devoted to the processing of stimulus form, not motion. Various modifications of motion stimuli can cause different combinations of motion, as well as form, mechanisms to be engaged. Thus the question of whether multiple streams influence first-order and second-order motion percepts needs to carefully address the functional role of these streams from the broader perspective of visual perception, not only their possible immediate influence on a relatively narrow set of motion percepts.

For example, Lu and Sperling have provided experimental evidence for a third-order motion system that requires feature tracking. A number of other experimentalists have also emphasized the role of feature tracking signals. Lu and Sperling noted that this system is slower than the first-order and second-order motion systems, operates interocularly as well as monocularly, requires much more stimulus contrast than first-order and second-order stimuli, and requires both bottom-up processing including interactions between form and motion pathways and top-down attentional priming. We have elsewhere argued that such “third-order motion” percepts are due to form-motion interactions that help to join complementary processing properties of the form and motion processing streams. Namely, the form stream uses precise orientational estimates to form emergent 3-D boundary and surface representations at precisely calibrated depths from an observer, but exhibits poor directional tracking properties. The motion system sacrifices
11 How Multiple-Scale ON and OFF Processing Help to Explain Other Second-Order Motion Data

The cross-talk between ON and OFF cells in lightening and darkening channels, competition between directional cells, and short-range and long-range filter stages can be used to explain other data that have previously been proposed to imply the existence of separate processing streams for processing Fourier and non-Fourier stimuli. Arguments for separate streams are often based upon an elaborated Reichardt model as the main processing stage for motion processing. For example, Lu and Sperling have reported data to identify three separate processing streams (or systems) for motion processing: a first-order system for Fourier stimuli such as moving luminance modulations, a second-order system for non-Fourier stimuli such as moving texture-contrast modulations, and a third-order system that tracks features. The first-order and second-order streams are identified to be monocular and bottom-up while the third-order stream is both monocular and binocular and can be influenced by top-down attentional priming.

Lu and Sperling mainly dealt with four kinds of motion stimuli: luminance stimuli that are first-order; texture stimuli that are second-order; depth stimuli that are presented interocularly (stereo); and motion-motion modulated stimuli that require feature tracking. In some experiments, these motion stimuli were modulated with a pedestal (a stationary sine wave). The main purpose of modulating luminance and texture stimuli with a pedestal was to remove features, thereby preventing these stimuli from being processed by a third-order tracking system. Their temporal-frequency sensitivity tests (Experiment 1) for these four kinds of stimuli show that both first-order and second-order systems are fast while the third-order system for depth and motion modulated stimuli is comparatively slow. The pedestal stimuli tests (Experiments 2 and 3) further confirmed the results from Experiment 1. These data agree with a single processing stream model for first-order and second-order motion stimuli such as ours. The third-order system is slow as it tracks features in the stimuli and requires interstream interactions such as between V2 and MT.

The relative phase dependence test (Experiment 4) examined directional judgments for superimposed Fourier and non-Fourier gratings as a function of relative spatial phase. If pedestal luminance modulated and texture modulated stimuli moved in opposite directions (pedestaled motion transparency test), then no motion was observed. This result is consistent with a single stream system for processing of both first-order and second-order stimuli. In particular, it agrees with our model’s proposal that competition between opponent direction cells occurs no later than the long-range filter stage. This model property is supported by neurophysiological data suggesting the opponent motion direction cells compete no later than cortical area MT.
The main evidence suggesting that first-order and second-order systems utilize separate channels came from the tests in which luminance-modulated and texture-modulated stimuli were presented together drifting in the same direction (Experiment 4). In one case, both stimuli had the same spatial frequency and temporal frequency. This case tested the hypothesis that both texture-modulated and luminance-modulated stimuli are computed by a first-order system with linear processing and half-wave rectification. In the other case, the parameters of the contrast-modulated stimulus remained the same, but the spatial and the temporal frequency of the luminance-modulated stimulus were only half that of the first case. This case tested the hypothesis that both stimuli are processed by a second-order system with nonlinear processing and full-wave rectification. The full-wave rectification would double the frequency of the luminance-modulated stimulus, thereby matching it to the texture-modulated stimulus. Interestingly, the stimuli in these cases were not modulated by the pedestal. The percent of correct direction-of-motion judgments of both stimuli together was determined for eight relative spatial phases. The test hypothesis was that, if both stimuli were processed by a single channel before the motion is computed, then their combined magnitude would depend on their relative phase. For example, stimuli with the same frequency but with opposite phase would cancel each other. Therefore, absence of any phase dependence would mean that these stimuli are processed by separate systems. To a good first approximation, they found no relative phase dependence in the first case, and a slight phase dependence in the second case, which they attributed to sine-wave luminance-modulated stimuli leaking into the second-order system. They concluded that separate channels compute motion for luminance-modulated and texture-modulated stimuli and these two streams are combined at a higher level to arrive at a single-valued representation of motion direction.

These conclusions are generally true for motion energy models based on elaborated Reichardt motion detectors, including those where the spatio-temporal signal is preprocessed by nonlinear filters followed by full-wave rectification. Taub et al. 110 nonetheless were able to successfully challenge the Lu and Sperling 14 conclusion that their data imply that separate first-order and second-order processing streams necessarily exist. Taub et al. 110 proposed a single processing stream model and used psychophysical experiments to estimate a functional form of its nonlinear processing to handle a large number of data, including the phase-dependence data of Lu and Sperling 14. They proposed the nonlinear processing to be compressive and asymmetric; i.e., it treats positive and negative contrasts differently. They also observed that if a large spatial filter was used before the nonlinear transformation, then the function appears to be more nearly linear. Taub et al. 110 also noted that Lu and Sperling 14 “measured the fraction of correct judgments, not motion energy, and the measurements were made in the range of 86%-90%-correct performance. In this range, the fraction correct is likely to be a compressive function of motion energy”, thus further reducing the likelihood of observing the phase dependence psychophysically.

A key difference between our model and the elaborated Reichardt model, among others, is that our model predicts the existence of lightening and darkening cells that transiently respond to local increases in brightness or darkness, respectively. We now note similarities between the way lightening and darkening cell process their inputs and the nonlinear transformation proposed by Taub et al. 110. In our model, on-center off-surround processing in the lightening and darkening channels allows the information from both ON and OFF cells in the center to interact with ON and OFF cells in the surround. The shunting competition causes spatial distribution of activity. The motion directions are computed independently in the lightening and darkening channels before they are pooled at the long-range filter stage. The inhibitory inputs are shunted at a value that is less than the excitatory inputs, thereby leading to asymmetric processing of excitatory and inhibitory signals. Also, the surround Gaussian filter is proposed to be spatially large, which allows the inputs to be presented linearly. Mathematical details and parameter values are given below. Thus, the
neural architecture of our model is supported by the experimental findings of Taub et al. They do not identify the existence of lightening and darkening cells. Nor do they propose the nonlinearity to occur at ON and OFF cells stage. On the other hand, Taub et al. do note that the nonlinear transformation could happen in two pathways that are mirror-images of each other. The lightening and darkening cells of our model does support (approximately) mirror-image processing due to ON and OFF processing.

Taub et al. also noted that “the Fourier and non-Fourier gratings were presented in alternate rows of raster display; this spatial separation would reduce interactions among the two kinds of gratings simply because they might tend to stimulate separate detectors”. In our model, the anisotropic spatial filters tuned in the direction-of-drift, which was the same for both the luminance-modulated and texture-modulated stimuli in the phase-dependence test, can detect the motion much more independently than could isotropic spatial filters, thus also helping to keep the phase-dependence small. All of these factors conspire to generate small phase dependence without necessarily processing first-order and second-order stimuli independently. Finally, if luminance and texture stimuli have different spatial and temporal frequencies, the different selectivities of multiple spatial scales and interscale competition would allow the system to compute the correct direction and speed of motion.

Lu and Sperling also performed interocular tests (Experiments 5 and 6) and observed that first-order and second-order motion were monocular processes, while depth and modulated motion stimuli required feature tracking and were not effected by interocular presentations. If this is true, then first-order and second-order processing must be handled before MT. This is consistent with our model’s hypothesis that lightening and darkening cells exist at an early stage before the long-range filter that converges on model MT cells. As per feature tracking to be both monocular and binocular, this is obvious in our model because feature tracking occurs before the long-range filter stage at which binocular fusion occurs.

A number of studies have used interleaved first-order and second-order motion stimuli. In these experiments, one frame of first-order stimulus is replaced by a frame of a second-order stimulus and the subjects are asked to report the direction of perceived motion. For example, Ledgeway and Smith used luminance-modulated bit noise as first-order stimulus and contrast-modulated bit noise as a second-order stimulus. They varied the spatial displacement as a fraction of spatial period of the modulating sine wave between frames and subjects were asked to report the direction of perceived motion. The results became ambiguous when the spatial shift between the frames was equal to quarter of the wave-length; i.e., the effective phase shift between the stimuli of same type equaled half of wavelength. They argued that, if first-order and second-order stimuli were processed by separate channels, the effective phase shift of 0.5 wavelength within the independent channels would cause ambiguous motion direction perception.

The authors noted that, because the two stimuli are not alike, their difference could result in motion cancellation in single channel models that use some sort of nonlinearity at an early stage of processing. Such a nonlinearity, which exists in essentially all motion models today, could also explain their data without requiring the assumption of two separate channels. In order to eliminate this possibility, they tried to make the two stimuli close in appearance and alter their modulation depth and intensity. However, these modifications influence the global nature of the second-order signal, making it similar to the first-order signal (e.g., they become similar in their global visibility).

The model described here is capable of capturing these differences at spatially local levels. In particular, these local differences in image intensities, though small, are captured by the lightening and darkening cells, which process information from surround as well as center, and can capture the transient effects of relative changes in the local brightness levels (see Section 4). This is qualitatively similar to our explanation of the G display when seen from near and far. In those experiments,
the grating shift was accompanied by an intensity contrast reversal. In interleaved experiments, the phase shift between frames is accompanied by replacing a contrast-modulated stimulus with a luminance-modulated stimulus, or vice versa. The local changes between these two types of stimuli are captured by the lightening and darkening cells. When the shift equals a quarter of the wavelength, as in the Γ display, it generates equivalent signals for both directions at the long-range filter stage, where the global motion signals are processed. Similarly, Mather and West 99 used intensity kinematograms as first-order stimuli and texture kinematograms as second-order stimuli in their version of interleaved experiments. The same arguments apply in those cases as well.

A number of studies have reported that temporal sensitivity is worse for second-order motion than first-order motion and therefore suggest that two processing streams are necessary 100–104. However, selective adaptation studies strongly suggest a single-processing channel 105, 106. Turano 108 reported that “the results support the view that signals generated from luminance-domain stimuli and from contrast-domain stimuli are processed by a common motion mechanism” (p 455). Holliday and Anderson 103 also found that adaptation tuning curves for first-order and second-order stimuli are similar at high temporal frequencies (more than 4 Hz) with maximal postadaptation near 12 Hz. For example, they concluded “the results are consistent with the hypothesis that fast second-order motion is detected by Fourier-type mechanisms, preceded by a nonlinearity, and slow second-order motion is detected by a process involving a comparison of local luminance features” (p 165). Lu and Sperling 114 have classified these data into three types of motion. They noted that the first-order and second-order are fast, while the third-order system is slow. As discussed above, these so called third-order stimuli may require more processing time because the percept requires form-motion interstream interactions such as between V2 and MT 15–17, 67.

Other experiments such as those by Chubb and Sperling 77 on drift-balanced stimuli and Harris and Smith 78 on OKN were discussed above in the light of model simulations.

12 Summary

A neural model of motion perception based upon magnocellular dynamics is developed to provide a unified explanation of key first-order and second-order motion percepts. This motion Boundary Contour System model does not invoke parallel Fourier and non-Fourier pathways. A single processing stream is sufficient if opponent ON and OFF channels exist that are capable of antagonistic rebound and that combine their results at suitably defined lightening and darkening cells whose outputs are pooled to derive a motion percept. The model thus does not require separate channels, with one detecting only first-order motion while the other detects only second-order motion. This result is in agreement with the data of Albright 33 showing that most of the cells at area MT are selective to both first-order and second-order motion stimuli. In addition:

1. The model explains why monkeys with lesions of the parvocellular but not magnocellular layers of the lateral geniculate nucleus are capable of detecting the correct direction of first-order motion 34. The model also predicts that such selective blocking would not effect the detection of the correct direction of second-order motion.

2. The model computes the correct direction of motion of a contrast-reversing noise field as an example of a second-order motion stimulus 77.

3. The model computes the opposite directions of motion for the Γ display when it is seen from near and far 12.
4. The model computes the correct direction of motion and tracks both edges of a moving bright bar moving on a background. The model tracks only the trailing edge of a moving bright bar if its ON channel is blocked \(^{38}\). The model predicts that blocking OFF bipolar cells would make direction-selective cortical cells insensitive to the trailing edge. Moreover, if a dark moving bar was used instead of a bright bar, then blocking ON (OFF) cells should make the direction-selective cells insensitive to the trailing (leading) edge.

5. The model qualitatively explains the data of Lu and Sperling \(^{14}\) on how directional judgments depend upon relative spatial phase, or spatial and temporal frequency.

6. The model predicts the existence of two testable classes of cells in the magnocellular processing stream, lightening and darkening cells, that transiently respond to local increase in brightness and darkness, respectively, no later than cortical area MT.

The present version of the motion Boundary Contour System incorporates transient OFF cell rebounds and lightening and darkening cells into a neural theory of motion perception that has earlier simulated a wide variety of data about short-range and long-range apparent motion \(^{10, 51}\), percepts of object speed and direction \(^{66, 67}\), and form-motion interactions \(^{15-17}\). The present results hereby show how a small set of properly configured neural mechanisms can be used to unify the explanation of a diverse set of motion data.

Figure 2: (a) The motion task used in Schiller et al. 34. Monkeys fixate a point in the middle of the screen that is filled with random dots. When dots in a certain position begin moving coherently, monkeys are trained to saccade to that position. (b) Experimental results: Results before any lesion are represented as control. Parvocellular lesions do not produce any deficit in performance. Magnocellular lesions reduce performance to chance. (Adapted from Schiller et al. 34)

Figure 3: Effect of APB on cortical directionally selective cells. (a) A wide bright bar slides to the right through a cell’s receptive field (RF), which is represented by the small circle. Bar edges are coded according to their spatial contrast (i.e., dark side on the left indicates a dark-light or DL edge, while dark side on the right indicates a light-dark or LD edge). (b) Luminance at the receptive field increases as the leading edge of the bar reaches the receptive field. Luminance decreases as the trailing edge reaches the receptive field. Before APB injection, the cell fires to both edges. Edge LD is the first one to cross the receptive field. After APB injection, the cell fires only at the passage of the trailing edge that indicates a decrease in luminance. (c) The bright bar now moves from right to left. (d) Now the first edge to cross the receptive field is the DL edge instead. Before APB injection, the cell again fires at passage of both edges. Responses are not as strong as when the bar was moving to the right, indicating that this cell is more selective to rightward motion than to leftward motion. After APB injection, the cell fires only at the passage of the trailing edge. (Adapted from Schiller 35)
